

Putting this site on your own domain

Everything needed to point the KØMNATA domain at the website, or to move the whole thing onto an account you own. No part of it is locked to us.

01

What this site actually is

Plain HTML, CSS, JavaScript and images. **No build step, no server, no database, no API keys.** The whole site is 16.4 MB of files in the `site/` folder, and a browser can open them straight off a disk.

That is the important thing for this handover: it will run on any static host, free ones included, and moving it is copying a folder.

The one thing it needs from a host is **byte range requests**, HTTP 206. The hero video will not play in Safari without them. Every real host does this.

Live at	<code>komnata-website.vercel.app</code>
Code	<code>github.com/FilippB-52/komnata-website</code>
Host	Vercel, project <code>komnata-website</code> , under the Hosy team
Deploys	automatically, on every push to <code>main</code>
Domain	not attached yet. The domain sits at Namecheap and still points elsewhere

02

Three ways to go

A Leave it where it is, just point the domain

Half an hour. Nothing moves, nothing can break, and the hosting costs you nothing where it is. Best if the night is close.

B KØMNATA takes over the hosting

The project moves to a KØMNATA Vercel account. You control the domain, the deploys and the analytics. About an hour. This is the one to pick if you want to own it properly.

C Move off Vercel completely

Netlify, Cloudflare Pages, GitHub Pages, or ordinary shared hosting over FTP. All of them work, because there is no build step. Only worth doing if you already pay for hosting somewhere.

Do A now, B after the party. Getting the domain live is the urgent part. Moving accounts is not, and doing both in the week of an event is how a site goes down on the night.

03

Route A: point the Namecheap domain here

Do it in this order. Adding the domain in Vercel **first** is what makes the rest exact.

Add the domain in Vercel

- 1 vercel.com, team **Hosy**, project **komnata-website**
- 2 Settings, then Domains
- 3 Type the domain, for example `komnata.c1ub` and `www.komnata.c1ub`, then Add

Vercel then shows **the exact DNS records to create**. Use those.

Do not copy an IP address out of a guide, or out of this document. Vercel's targets are not fixed. Checked while writing this, their published CNAME target resolved to two addresses, neither of which was the one usually quoted online. The panel shows what is correct today, for this project.

Put those records into Namecheap

- 1 namecheap.com, sign in, Domain List, **Manage** next to the domain
- 2 Open the **Advanced DNS** tab
- 3 Delete any existing A or CNAME record on @ and on www, including Namecheap's own parking page record
- 4 Add what Vercel showed you. Normally that is two records:
 - an **A Record**, host @, value = the IP Vercel gave
 - a **CNAME Record**, host www, value = the target Vercel gave
- 5 TTL: Automatic. Save.

Wait, then check

DNS usually takes ten minutes to an hour, occasionally longer. Vercel's Domains page shows a tick once it sees the records, and issues the HTTPS certificate on its own. There is nothing to do for SSL.

Working means the domain opens the site and the browser shows a padlock.

Route B: move it to a KØMNATA account

- 1 **Make a Vercel account** at vercel.com. The free Hobby plan is enough: this site is static and runs no server code.
- 2 **Make a GitHub account**. Filipp transfers the repository to it (GitHub, repo, Settings, Transfer ownership), or you fork it.
- 3 In your Vercel: **Add New, Project**, import the repository.
- 4 On the import screen set **Output Directory to site**. Leave the build command empty. Everything else is already in `vercel.json` in the repo.
- 5 Deploy, and check the `.vercel.app` address works.
- 6 Then do the Route A DNS steps against **your** project, and remove the domain from ours so the two do not fight over it.

What has to change hands

ITEM	WHERE IT IS	WHAT IT IS FOR
The repository	github.com/FilippB-52/komnata-website	everything
Namecheap login	you already have this	the DNS records
Meta Pixel ID	2480966919077348	so your ads team can claim it in Meta Business Manager
Patt event link	already in the code	the ticket button
Spotify playlists	already in the code	the record player
Social handles	already in the code	the Telegram and Instagram cards
Source artwork	Source files/	re-exporting headings or photos later

Everything except the Namecheap login is already inside the repository. **Hand over the repo and you have the site.**

Not handed over, because it does not exist: there are no API keys, no environment variables, no database and no admin login. Nothing to rotate, nothing left behind.

Four things that will break it

Do not serve the repository root.

Only `site/` is the website. The folders beside it hold source artwork, previous versions and the original footage. `vercel.json` already pins this; any other host has to be told.

Do not test with `python -m http.server`.

It answers range requests with 200 instead of 206, so Safari refuses to play the hero video and the site looks broken for no reason. Use `npx serve -l 5180 site`.

After editing CSS or JS, raise the `?v=` number.

Those files are cached for a year on purpose, and the number is how a visitor is told to fetch the new one. It sits on the tag in `site/index.html`. Without it, people keep the old file and swear nothing changed.

Keep data-buy on the ticket buttons.

That attribute is what fires the Meta Pixel's `InitiateCheckout` event. Remove it and every sale that starts on the site silently stops being counted.

If something goes wrong

The domain shows a Namecheap parking page

Their default record is still there. Delete every A and CNAME on `@` and `www`, then re-add Vercel's.

Vercel says "Invalid Configuration"

The records do not match. Compare them character by character against what the Domains page is asking for.

The site loads but the video does not play

The host is not answering range requests with 206.

A change was deployed and nobody can see it

The `?v=` number was not raised.

Something needs rolling back

Background `versions/` and `Rollback points/` in the repo each hold a previous state with its own restore instructions, and the full history is in git.
